(Received 3 June 2010; published 13 September 2010)

The satellite-borne experiment PAMELA has been used to make a new measurement of the cosmic-ray antiproton flux and the antiproton-to-proton flux ratio which extends previously published measurements down to 60 MeV and up to 180 GeV in kinetic energy. During 850 days of data acquisition approximately 1500 antiprotons were observed. The measurements are consistent with purely secondary production of antiprotons in the Galaxy. More precise secondary production models are required for a complete interpretation of the results.

Antiprotons and positrons are a small but not negligible component of the cosmic radiation. They can be produced in the interactions between cosmic-ray nuclei and the interstellar matter. Detailed measurements of the cosmic-ray antiproton energy spectrum therefore provide important information concerning the origin and propagation of cosmic rays. Exotic sources of primary antiprotons such as the annihilation of dark matter particles [1–3] and the evaporation of primordial black holes [4,5] can also be probed. The theoretical energy spectrum of secondary antiprotons has a distinct peak around 2 GeV and rapidly decreases towards lower energies due to the kinematic constraints on the antiproton production. At higher energies the spectrum is slightly steeper than that of the parent protons (e.g., see [6]), which results in a slight decrease of the antiproton-to-proton flux ratio.

Since July 2006, PAMELA (a Payload for Antimatter Matter Exploration and Light-nuclei Astrophysics) has been measuring the antiparticle component of the cosmic radiation. A previous PAMELA measurement of the antiproton-to-proton flux ratio between 1.5 and 100 GeV [7] was found to follow the expectation from secondary production calculations. However, the positron fraction [8,9] measured in the same energy range showed a clear deviation from secondary production models. In order to explain these results both astrophysical objects (e.g., pulsars) and dark matter have been proposed as positron sources (e.g., [10]). A contribution from pulsars would naturally increase the positron and electron abundances without affecting the antiproton component. Other astrophysical models [11] have been proposed to explain the PAMELA positron results but produce an increase in the
antiproton component at very high energies ($\geq 100$ GeV). A dark matter contribution may require pure leptonic
annihilation channels, e.g. [12], or the introduction of a
new dark sector of forces, e.g. [13]. In [14] it is noted that
any signal in the antiproton energy spectrum may be
hidden due to incomplete modeling of secondary produc-
tion and cosmic-ray propagation. A detailed measurement
of the antiproton energy spectrum over a large energy
range is therefore of great interest.

The PAMELA experiment [10,15] comprises (from top
to bottom): a time-of-flight system, a magnetic spectrome-
ter with silicon tracker planes, an anticoincidence system,
an electromagnetic imaging calorimeter, a shower tail
catcher scintillator, and a neutron detector. These compo-
ments are housed inside a pressurized container attached to
the Russian Resurs-DK1 satellite, which was launched on
June 15th 2006. The orbit is elliptical and semipolar, with
an inclination of 70.0° and an altitude varying between
350 km and 610 km.

We report on the cosmic-ray antiproton flux over the
widest energy range ever achieved: 60 MeV to 180 GeV.
We also confirm and extend the previously published
PAMELA antiproton-to-proton flux ratio measurement
[7] to the same energy range. Data were acquired from
July 2006 to December 2008 (850 days), corresponding to
$>10^9$ triggers. Triggered events were selected for analysis
if the reconstructed rigidity exceeded the vertical geomag-
netic cutoff (estimated using the satellite orbital informa-
tion) by a factor of 1.3. Downward-going charge-one
particles were selected using the time-of-flight and spec-
trometer data. Time-of-flight information was also used to
select low velocity (anti)protons while electrons were
rejected using the electromagnetic calorimeter informa-
tion, as described in [7]. The remaining electron contami-
nation was estimated to be negligible while contamination
from locally produced pions was found to be about 10%
between 1 and 3 GV/c and negligible at lower and higher
rigidities [7,16].

The highest energy at which antiprotons can be unam-
biguously measured by PAMELA is determined by the
contamination of “spillover” protons which are recon-
structed with an incorrect sign of curvature either due to
the finite spectrometer resolution or scattering in the spec-
trometer planes. To reduce this contamination, strict
requirements were applied on the quality of the tracks
reconstructed in the spectrometer. For example, tracks
accompanied by $\delta$-ray emission were discarded to avoid
poorly reconstructed coordinates on the silicon planes of

**Table I.** Summary of antiproton results. Antiproton fluxes ($\times 10^{-3}$ particles/(m$^2$ sr s GeV)) and antiproton-to-proton flux ratios ($\times 10^{-5}$). The upper limits are 90% confidence levels. The first and second errors represent the statistical and systematic uncertainties, respectively.
the spectrometer. For each track the maximum detectable rigidity (MDR) was evaluated on an event-by-event basis by propagating the estimated coordinate errors and taking into account the track topology. The MDR was required to be 6 times larger than the measured rigidity. This allowed the antiproton measurement to be extended up to 180 GeV/c with acceptable contamination from spillover protons. The contamination was estimated using the GEANT3 package [17]. The simulation contains an accurate representation of the geometry and performance of the PAMELA detectors. For the spectrometer [18] the measured noise of each silicon plane and performance variations over the duration of the measurement were accounted for. The simulation code was validated by comparing the distributions of several significant variables (e.g., coordinate residuals, $\chi^2$ and the covariance matrix from the track fitting) with those obtained from real data. The high-energy region of the deflection distribution was studied before applying the MDR selection and agreement within 20% was found between data and simulation. This difference was taken as a systematic uncertainty on the spillover contamination which was estimated to be $\approx 30\%$ for the rigidity interval 100–180 GeV/c.

The efficiencies were carefully studied using both experimental and simulated data [16,19,20]. The time dependence of the detector performance (and therefore also efficiency) was studied using proton samples collected during 2 month long periods. The average global selection efficiency was measured to be $\approx 30\%$. The number of (anti)protons rejected by the selection criteria due to interactions and energy loss within the detector systems was estimated using the simulation. The number of antiprotons lost due to this selection is energy dependent and varies from $\approx 10\%$ below 1 GeV to $\approx 6\%$ above 50 GeV. The antiproton flux was obtained by considering the geometrical factor (estimated both analytically and with simulations) and the total live time which is provided by an on-board clock that times the periods during which the apparatus is waiting for a trigger.

The energy-binned antiproton fluxes and antiproton-to-proton flux ratios are given in Table I. The spectrometer resolution has not been unfolded and a systematic uncertainty is included to account for this. Contamination from pions and spillover protons has been subtracted from the results. The first and second errors in the table represent the statistical and systematic uncertainties, respectively. The total systematic uncertainty was obtained quadratically summing the various systematic errors considered: acceptance, contamination, efficiency estimation, energy losses, interactions and spectrum unfolding.

Figure 1 shows the antiproton energy spectrum and Fig. 2 shows the antiproton-to-proton flux ratio measured by PAMELA along with other recent experimental data [21–26] and theoretical calculations assuming pure secondary production of antiprotons during the propagation of cosmic rays in the Galaxy. The curves were calculated for solar minimum, which is appropriate for the PAMELA data taking period, using the force field approximation [27,28].

The PAMELA results reproduce the expected peak around 2 GeV in the antiproton flux and are in overall agreement with pure secondary calculations. The experimental uncertainties are smaller than the spread in the different theoretical curves and, therefore, provide important constrains on parameters relevant for secondary production calculations. For example, the antiproton flux bands from Donato et al. [31] presented in Fig. 1 show uncertainties on the propagation parameters (dotted lines) and antiproton production cross sections (dashed lines) and indicate larger uncertainties than those present in the PAMELA measurements. Figure 3 shows the PAMELA antiproton-to-proton flux ratio compared with a calculation [14] (dashed line) including both a primary antiproton component from the annihilation of 180 GeV winolike neutralinos and secondary antiprotons. This model, based on the nonthermal production of dark matter in the early Universe, was proposed to explain the high-energy rise in the PAMELA positron fraction [8]. As shown by the dashed line in Fig. 3, a reasonable choice of GALPROP [32] propagation parameters (dashed-dotted line) allows a
good description of PAMELA antiproton data with the inclusion of the wino-annihilation signal. Given current uncertainties on propagation parameters, this primary component cannot be ruled out. It has also been suggested that the PAMELA positron data can be explained without invoking a primary component. This is possible if secondary production takes place in the same region where cosmic rays are being accelerated [11]. An increase in the antiproton [33] and secondary nuclei abundances [34] are also predicted in this model. The solid line in Fig. 3 shows the prediction for the high-energy antiproton-to-proton flux ratio. While this theoretical prediction is in good agreement with the PAMELA data, in this energy region it does not differ significantly from the expectation for standard secondary production models. Comparisons with experimental secondary cosmic-ray nuclei data are needed along with higher energy antiproton measurements. New data on the boron-to-carbon ratio measured by PAMELA will soon become available, while the antiproton spectrum is likely to be probed at higher energies by AMS-02 experiment [35] which will soon be placed on the International Space Station.

We have measured the antiproton energy spectrum and the antiproton-to-proton flux ratio over the most extended energy range ever achieved and with no atmospheric overburden. Our results are consistent with pure secondary production of antiprotons during the propagation of cosmic rays in the Galaxy. We note that the quality of our data surpasses the current precision of the theoretical modeling of the cosmic-ray acceleration and propagation mechanisms. Improved models are needed to allow the full significance of these experimental results to be understood.

While more precise models of solar modulation, accounting for effects such as sign-charge dependence of the modulation, exist (e.g., Refs. [29,30]), the force field model is a simple approach that provides a reasonably good approximation of the solar modulation above 1–2 GeV.
